1.0 INTRODUCTION AND PURPOSE

1.0 INTRODUCTION AND PURPOSE

It is the goal of the Federal Clean Water Act (PL 95-217) to restore and maintain the biological integrity of the nation's waters. Biological monitoring provides the most reliable measure of the attainment of this goal, i.e., water quality that provides for the protection and propagation of fish, shellfish and wildlife.

Sampling and analyzing aquatic life provides information on water quality that can easily escape standard physico-chemical sampling. The organisms themselves are efficient in-stream monitors, for their lives reflect the cumulative impact of pollution on the waterbody. They are valuable in revealing transient pollution episodes such as oil spills and brief dissolved oxygen sags. For the same reason they are the best means of measuring long term trends in a waterbody. In addition, the presence of specific indicator organisms may infer the presence of particular chemicals not included in routine analysis or in quantities below detection limits of chemical testing.

Aquatic biota are usually collected and analyzed by community. These communities include plankton, periphyton, macrophyton, macroinvertebrates and fish. The communities are used alone or in combinations to assess specific water quality problems such as thermal pollution, toxics, and eutrophication. The analysis of the samples includes taxonomic identification for diversity indices, water quality indices, tropnic level and indicator organism analysis. Plant pigments are extracted for chlorophyll analysis and animal tissues are tested for bioconcentration of chemicals. The overall health and appearance of the organisms is used to detect chronic toxicity and genotoxic effects (carcinogens, mutagens and tetratogens). Standard laboratory organisms are also used in situ and in vitro to measure toxicity. Bacteria, algae, macroinvertebrates and fish are all commonly used for this purpose.

Biological monitoring can be more cost effective than chemical screening, more reliable at measuring total pollutant loads, more sensitive to extreme conditions and more faithful to the goal of the Act, than other forms of monitoring. However, the relationship between the biota and the environment is subtle and complex and by no means completely understood. Results of biological investigations are often qualitative, and even quantitative studies are open to interpretation. Therefore biological monitoring data are used to complement physico-chemical data and not replace them.

The methods of monitoring and analysis are evolving and may differ among investigators. At best, procedures used by the Division of Water Pollution Control are fully documented in this Standard Operating Procedures document, so that those attempting interpretation will be fully informed, and temper their conclusions accordingly.

2.1 STREAM CLASSIFICATION

2.1.1 INTRODUCTION AND PURPOSE

This program has been developed to systematically sample and classify the Commonwealth's rivers and streams. Each survey qualitatively provides documentation of a specific watercourses' physical and chemical characteristics and predominant biological components. These data can be used - on a stream or site-specific basis - to determine water-use classifications in accordance with Massachusetts Surface Water Quality Standards.

2.1.2 OBJECTIVES

- 1. To identify, demonstrate, and standardize methods and procedures for the collection and analyses of stream habitat data;
- 2. to characterize rivers, streams, and related aquatic habitats (e.g., river impoundments) hydrophysically and chemically;
- 3. to qualitatively document the dominant floral and faunal components or communities of streams and stream-side habitats;
- 4. to segment and classify rivers and streams into major habitats for the purpose of water-use designation;
- 5. to provide supplementary information to other programs to aid in regulatory and enforcement actions, and evaluating special problems; and
- 6. to collect and reference plant and animal specimens for future study, and determine their state-wide distribution.

2.1.3 APPROACH

Preliminary planning and analysis first divides the river or stream into longitudinal zones - or subsystems, i.e., tidal, lower perennial, upper perennial, intermittent, and others (e.g., canals, ditches) - according to morphometric and hydrologic characteristics derived from USGS topographic maps. Physico-chemical and biological field collections are made, in most instances, at locations - or sites - determined after initial evaluation and field reconnaissance (see: "Data Record Sheets"). Specific sampling locations are arranged to cover significant and representative lotic-water and other related macrohabitats. Field dates, particularly for biological sampling, are generally during the period April to October, in order to take advantage of plant and animal availability. All field sampling is qualitative in nature, unless special needs dictate otherwise. Data collected are recorded for each community on individual standard field sheets (see: "Biological Field and Laboratory Methods").

2.1.4 PARAMETRIC COVERAGE

Physical and chemical data are collected, including: stream reach width and depth; stream reach and floodplain substrate character; stream temperature; water transparency; and water chemistry. Sampling of phytoplankton and periphyton, aquatic vascular plants, streamside and riparian vegetation, and aquatic macroinvertebrates is performed at each site.

2.2 AQUATIC MACROINVERTEBRATE RAPID ASSESSMENT

2.2.1 INTRODUCTION AND PURPOSE

Macroinvertebrate rapid assessment surveys involve the use of qualitative and semi-quantitative sampling methods designed to minimize laboratory time requirements for taxonomic identification and enumeration of aquatic macroinvertebrate organisms.

2.2.2 OBJECTIVES

- 1. To provide standardized methods and procedures for assessing the impacts of organic and toxic pollution on aquatic macroinvertebrates;
- 2. to obtain reliable biological water quality information to supplement the collection of standard physico-chemical water quality data; and
- 3. to provide the basis for making relative comparisons pertaining to water quality conditions between sampling stations and/or to document long-term trends at fixed sites.

2.2.3 APPROACH

While rapid assessments make use of the qualitative analysis of periphyton, aquatic and wetland vegetation, and fish communities, specific semi-quantitative sampling and analytical methods have been developed for use in assessing the macroinvertebrate community.

An upstream-downstream sampling regime is employed whereby known or suspected sources of pollution are bracketed. Selected aquatic communities are assessed and compared with unimpacted control (or reference) communities. Conclusions relative to water quality condition are drawn from a knowledge of the environmental requirements and pollution ecology of the individual taxa or assemblages encountered.

For macroinvertebrate rapid assessment the components of a 100 organism subset are identified to genus or species level whenever possible. At a minimum the following parameters are then calculated:

- (1) Richness (total number of taxa)
- (2) Ordinal Richness (total number of orders represented)
- (3) Modified Hilsenhoff Biotic Index (HBI) calculated for each sampling site after individual arthropod taxa (insects, amphipods, isopods) are assigned values from zero to five based on their relative tolerances to organic pollution.

These data are then combined with a consideration of:

- 1. a listing of the five most abundant taxa;
- 2. the known ecological requirements of the dominant assemblage; and
- 3. how balanced the community is.

Water quality is then classified according to the following provisional guidelines developed by the New York State Department of Health.

- 1. Non-Impacted Diverse fauna, at least 30 species; HBI less than 2.00. Ephemeroptera, Plecoptera, and Trichoptera are well represented. Dominant species are intolerant or facultative; no species accounts for more than 25% of the individuals. Oligochaetes comprise less than 20% of the individuals.
- 2. Slightly Impacted Species richness usually 20-30; HBI 2.00-3.00. Ephemeroptera and Plecoptera may be restricted; oligochaetes may comprise over 20% of the individuals. Dominant species are mostly facultative. Fauna often not so well-balanced, often with one species comprising more than 25% of the individuals.
- 3. Moderately Impacted Species richness 10-20; HBI 3.00-4.00. Ephemeroptera and Plecoptera rare or absent, Trichoptera often restricted. The most abundant taxa are facultative or tolerant species. Oligochaetes usually comprise at least 20% of the individuals. Individuals of the genera Asellus or Simulium may be numerous.
- 4. Severely Impacted Less than 10 taxa present; HBI greater than 4.00. Ephemeroptera, Plecoptera, and Trichoptera rare or absent; fauna often restricted to chironomids and oligochaetes. Dominant organisms are almost all tolerant species. Fauna usually greatly imbalanced, with one species comprising more than 35% of the individuals.

The profiles listed are intended as general guidelines, and not strict limitations. In some cases the characteristics of a fauna may span two or three categories, e.g., one with 25 species, a biotic index value of 3.30, and the dominant species comprising 40% of the individuals. In such cases a consensus must be reached by examining the integrity of each component and weighing these against field observations.

2.2.4 PARAMETRIC COVERAGE

Rapid assessment surveys include, at a minimum, semi-quantitative aquatic macroinvertebrate sampling and water temperature determinations. However, qualitative analyses of the algae, macrophyte, and fish communities may also be conducted. Often, flow measurements, substrate characterization, and water chemistry sampling are conducted to supplement the results of biological sampling.

2.3 SITE ASSESSMENT

2.3.1 INTRODUCTION AND PURPOSE

While site assessments make use of a number of qualitative and semiquantitative methods borrowed from stream classification and/or rapid assessment protocols, they may also be expanded to include quantitative sampling and analytical procedures. In fact, site assessment surveys may range in scope from a qualitative assessment of the impact of a single wastewater discharge on a single aquatic community to intensive quantitative assessments of one or more communities. The latter are labor and resource intensive and are limited to those situations where the need exists for statistically derived statements of confidence in the results.

2.3.2 OBJECTIVES

- 1. To provide an adequate data base for making quantitative determinations of standing crop, biomass, or measures of community structure such as species diversity and richness;
- 2. to provide sufficient data for testing for significant differences between communities using appropriate statistical methods;
- 3. to provide standard methods for assessing the impacts of pollution on aquatic biota and water uses; and
- 4. to supplement physico-chemical water quality data with biological information.

2.3.3 APPROACH

Whenever possible, sampling stations are located upstream and downstream from known or suspected sources of pollution or other factors that might impact water quality conditions. The underlying assumption is made that, if all other environmental factors remain constant, a change in water chemistry will alter downstream community structure or biomass. Therefore, impact assessment is carried out by making community structural comparisons between upstream or nearby reference communities and downstream communities.

Measures of community structure to be employed are selected on a case-by-case basis according to the requirements of individual site assessments. Parameters include 1) abundance; 2) taxonomic richness; 3) evenness; and 4) diversity (e.g., Shannon Weaver H1). Comparisons of communities between sites are made using the above measures and standard significance tests such as t-tests.

Less intensive site assessments involving the use of qualitative or semiquantitative techniques are conducted according to the methods presented in previous sections for stream classification and rapid assessment surveys.

2.3.4 PARAMETRIC COVERAGE

Site assessments may involve the use of qualitative, semi-quantitative, or quantitative analyses of one or more of the following communities: phytoplankton; periphyton; macrophyton; macroinvertebrates; or fish. Biological stream sampling is supplemented, as deemed appropriate, by hydrological and physico-chemical assessments such as the determination of stream width, depth, flow, water temperature, substrate characterization, and chemical analyses.

2.3.5 QUANTITATIVE DATA ANALYSES

Definitions of some of the more commonly used indices of community structure are presented below.

Abundance

Two abundance measures are often used (1) the sum total of individuals found in all taxonomic groups in a particular data set (termed "total numbers"); and (2) the relative proportion of individuals found in different taxonomic categories (termed "relative abundance").

If a relationship between productivity and numbers of individuals can be established, increases from control to test sites in the total number of organisms found may be a result of increased nutrient availability. Decreases in this measure may be related to changes in nutrients and/or the influence of toxic substances. Changes in the relative abundance of major taxonomic groups may be related to habitat alterations between sites. When changes in the relative abundance of major groups are accompanied by a decrease in richness (see below) they may be due to either changes in nutrient availability and/or to toxic stress.

Taxonomic Richness

This term refers to the number of different taxonomic groups in a particular sample. Comparisons of richness are based on the assumption that physiological stress (defined as those instances under which environmental conditions such as temperature, oxygen concentration, pH, etc., exceed the tolerance limits of an individual) due to a toxic discharge can reduce the number of taxa originally inhabiting a certain area.

Richness of a sample collection is positively correlated with sampling effort. As area sampled, time spent sampling, and/or number of organisms collected is increased, the number of different taxa encountered also increases. For these reasons, comparisons should only be made between data sets for which sampling effort is similar or nearly so.

Evenness

This is a measure of the distribution of individual organisms over different taxonomic categories. Most evenness indices range from a value of zero to 1.0, with a completely uniform distribution yielding a value of 1.0.

Precision Data -

$$1. \quad S = \sqrt{\frac{\sum (x-m)^2}{n-1}}$$

Where:

S = Standard deviation

M = Mean (average)

X = Count

2. $C_2 = \frac{s}{m}$ or

n = Number of fields

$$\sqrt{\frac{\sum_{x}^{2} - n}{\frac{M^{2}}{n-1}}}$$

Where C_v = Coefficient of variation

3. P = % standard deviation of mean = $\frac{100c_V}{\sqrt{n}}$

- 4. $C_{\rm V}$ must be 0.317 or less if results in a 10-field count are to be \pm 10% within a 2/3 probability and a practical certainty (95%) of \pm 20% precision error.
- 5. Using past data it was found that if ten fields are counted:

 $C_V = 1.0$ or \pm 31.7% error was found in 90% of samples 0.7 or \pm 22% error was found in 75% of samples 0.45 or \pm 14% error was found in 50% of samples 0.317 or \pm 10% error was found in 33% of samples

On the average, a third of random samples were within $\pm 10\%$ error when 10 fields were counted, and half were within $\pm 14\%$.

6. $P = The Standard error of count (percent) and is found in the log-log plot of <math>C_V$ versus n.

3.1 PHYTOPLANKTON

3.1.1 <u>DEFINITION</u>: Phytoplankton are the algae of lakes and large rivers that live suspended in the water. They are chlorophyll-bearing, unicellular organisms which have no true roots, stems, or leaves. They occur in free-living, colonial, frond-like or filamentous forms and vary in size from unicells 0.5 microns in diameter to the macroscopic seaweeds. Algae are generally grouped into the Divisions (and classes) Euglenophyta (Euglenophyceae); Chlorophyta (Chlorophyceae, Charophyceae); Rhodophyta (Rhodophyceae); Cyanophyta (Myxophyceae); Pyrrophyta (Desmokantae, Dinophyceae); Chrysophyta (Xanthophyceae, Chrysophyceae, Bacillariophyceae); Phaeophyta (Phaeophyceae); and Cryptophyta (Cryptophyceae).

3.1.2 OBJECTIVES

- 1. To document the existing phytoplankton community and determine long-term (yearly) and short-term (seasonal) trends;
- 2. to evaluate direct effects on water composition including dissolved oxygen, pH, hardness, and optical properties;
- 3. to assess conditions affecting the general condition of water quality including noxious and toxic conditions, offensive tastes and odors;
- 4. to identify indicators of trophic status, organic enrichment and specific chemical contamination; and
- 5. to quantify autotrophic biomass and make inferences concerning productivity.

3.1.3 FIELD SAMPLING

Samples for phytoplankton analyses are collected in clean one-liter bottles made of plastic or glass, that have been rinsed with sample water. Approximately one-half liter of sample water is collected.

In rivers that are mixed vertically and horizontally, samples are collected midstream 0.5 to 1.0 meters (m) below the surface. In lakes and impoundments, samples are collected at the "deep-hole" station. If the lake is thermally unstratified the sample is collected 0.5-1.0 m below the surface. If the lake is thermally stratified, an *ntegrated column sample is collected by lowering a one centimeter (approximately) ID plastic tube (with a weight attached) to the thermocline zone, pinched below the miniscus and raised into the boat. The sample is then drained into a clean and rinsed collection bottle. This procedure is repeated until one-half liter of water is collected. All samples are cooled to 4°C and placed in the dark following collection.

For special studies in riverine and lacustrine habitats, samples are collected from major depth zones or water masses. Sampling depths at each site are determined by specific conditions. In shallow areas (2-3 m), subsurface sampling is generally conducted. In deeper areas samples are collected at regular intervals at depths throughout the euphotic zone.

Pertinent information collected and recorded in the field includes meteorological data (cloud cover, wind speed and direction, air temperature); surface water conditions; water color, turbidity, odors; total depth at station; and other descriptive information.

The frequency of sampling is dependent on the intent of the study as well as the range of seasonal fluctuations, the immediate meteorological conditions, adequacy of equipment, and availability of personnel. In tidally-influenced habitats, phytoplankton samples are collected at all tide stages, particularly at the end and the beginning of both the flood and ebb tides.

3.1.4 LABORATORY ANALYSES

Sample Preservation

Phytoplankton samples collected in the field are cooled to 4°C and kept in the dark in transit to the laboratory. Upon arrival at the laboratory, they are placed in a refrigerator until further processing. Samples are generally analyzed on the day of collection. Samples not analyzed on the day of collection are stored in a refrigerator overnight with the caps loosened to allow gas exchange. Samples stored for more than 48-hours are fixed by the following methods and preservatives:

- 1. Lugol's solution: For short-term storage, 0.3 ml Lugol's solution is added per 100 ml of sample aliquot and stored in the dark. For long-term storage, 0.7 ml Lugol's solution is added per 100 ml of sample. [Lugol's solution is prepared by dissolving 20 grams (g) potassium iodide (KI) and 10 g iodine crystals in 200 ml distilled water containing 20 ml glacial acetic acid].
- 2. Formalin: To preserve samples, 40 ml buffered formalin is added to one liter of sample.
- 3. M³ Fixative: For preservation, 20 ml M³ fixative is added to one liter of sample and stored in the dark. [M³ is prepared by dissolving 5 g KI, 10 g iodine, 50 ml glacial acetic acid, and 250 ml formalin in one liter of distilled water].

Color -

Cupric sulfate solution is added to the sample to preserve color [Cupric solution is prepared by dissolving 21 g cupric sulfate in 100 ml distilled water].

Clumping -

To prevent clumping, a detergent solution is added to the sample [20 ml liquid detergent is added to 100 ml distilled water].

Phytoplankton Examination

Log-In Procedure -

- 1) Each sample is assigned a number and logged in as it is brought into the laboratory. The numbers are in consecutive order and are recorded both on the sample tag and in a notebook (log book).
- 2) Next to the number in the log book are also recorded the station number and location, date collected, date analyzed, initials of collector, type of samples, sample depth, and analyses requested, i.e., chlorophyll and/or algal identifications.

Phytoplankton Examination Equipment List -

- 1) Microscope capable of 200x power with working distance greater than 1 mm.
- 2) Sedgwick Rafter (S-R) counting cells
- 3) Whipple micrometer reticule
- 4) Stage micrometer
- 5) Pipettes
- 6) Bench sheets
- 7) Lens paper

Procedure for Filling the Sedgwick-Rafter Cell -

- 1) Place the cover glass diagonally across the cell.
- 2) Use large-bore 1 ml pipette to fill the S-R cell.
- 3) Place tip of the pipette in the corner of the S-R cell and slowly release the pressure of your finger on the end of the pipette. The cover slip will then rotate and cover the sample.
- 4) To reduce error:
 - a. Do not overfill the cell which would yield a depth greater than 1 mm.
 - b. Do not allow large air bubbles to form. To prevent the formation of these air spaces, a drop of distilled water is placed on the edge of the cover glass occasionally during the microscopic examination.

Procedure for Phytoplankton Examination -

- 1) Shake the sample bottle to mix well.
- 2) Rinse 1 ml pipette with distilled water (inside and out) and three times with sample water.
- 3) Fill counting cell with 1 ml of sample water (see: "Procedure for Filling the Sedgwick Rafter Cell").
- 4) Allow sample to settle for 15 minutes (the settling rate for algae is 4 mm/hr; since the depth of the counting cell is 1 mm, a 15 minute settling time is used.
- 5) While sample is settling, prepare a microscopic slide or Palmer cell which will allow you to view the sample at a higher power. List the algal genera identified.
- 6) Use the keys to determine unknown organisms; particularly dominant ones.
- 7) Scan the Sedgwick-Rafter counting cell at 4x and determine need for concentration or dilution.
- 8) At 200x find the edge of the counting cell and focus on the top of the cell. Continue turning the coarse focusing knob on the microscope until the bottom of the cell comes into focus.
- 9) At least two strips in the S-R counting cell must be counted.
- 10) Counts are done on both the bottom of the cell and the top or underside of the cover slip.
- 11) Identify and count all the algae that are located in the Whipple grid.

 Algae which are half in and half out of the top of the grid should be included in the count. Algae which are half in and half out of the bottom of the grid are not included in the count.
- 12) If the algal density appears to be high then fields can be counted instead of strips. A field is represented by a Whipple grid. Ten fields on two slides are counted and then averaged.
- 13) A strip is represented by the width of Whipple grid and the length of a Sedgwick-Rafter cell.

Explanation of the Phytoplankton Examination Sheet -

(Refer to: "Phytoplankton Examination" Form)

- 1) Line 1 station location, station number, date of collection
- 2) Line 2 initials of analyst, milliliters of sample, which will be either 1 ml or the total concentrated, type of count, i.e., fields or strips and the date of analysis.

- 3) Lab number the number assigned the sample by the investigating laboratory (see: "Log-In Procedures").
- 4) Bottom two lines chlorophyll in mg/m³, total live algae (cells/ml), multiplication factor (S-R) for the particular microscope and power used, microscope manufacturer and type, the microscope power used (10x, 20x, etc.), type of preservative used, and a box for the initials of the person who does the quality control check of the multiplication and addition on the examination sheet.
- 5) Center of the phytoplankton examination sheet seven algal classes and eight types are delineated. Identifications are recorded under the organism column, running counts are recorded under counts. The running counts are tallied and multiplied by the S-R factor to obtain totals in cells/ml. A total is given for each class and type as well as for the sample.

Determination of the S-R Factor -

When strip counts or field counts are done on a Sedgwick-Rafter counting cell, only a portion of the l ml sample is examined. Therefore, a calibration of "S-R" factor must be determined. The following formula is used in this calibration:

S-R factor (strip count) = $\frac{1000 \text{ mm}^3}{\text{LxWxDxS}}$

where: L = length of a strip (mm)
S-R cell is 500 mm long

W = width of a strip which is the
Whipple grid image width (determined by using a stage micrometer)

D = depth of chamber (1 mm)

S = number of strips counted

The S-R (strip count) times C, the number of organisms counted (tally) equals the number of algae per milliliter.

units/ml = S-R (strip count) $x \in \mathbb{C}$

The S-R factor (field count) is calculated by using the following formula:

S-R factor (field count) = $\frac{1000}{A \times D \times F}$ mm³

where: A = area of a field, which is the Whipple grid image area

 $D = depth \ of \ chamber (1 mm)$

F = number of field counts

The number of algae per ml equals the S-R (field count) times C, the number of organisms counted (tally).

Units/ml = S-R (field count) x C

Procedure for Phytoplankton Counts -

In the unit (or clump) count each cell or colonial group of cells receives one unit.

Examples:

- 1. Anacystis one unit per clump
- 2. Anabaena one unit per chain
- 3. "Filamentous green" one unit per filament
- 4. Scenedesmus one unit each (4, 8, 16 etc., celled organism.)
- 5. <u>Fragilaria</u> and <u>Melosira</u> count each cell (may be best to average the area for a single cell and divide into total area.)
- 6. Asterionella each "arm" one unit
- 7. Dinobryon each colony one unit.

An attempt is made to identify all organisms to generic level. If this can not be accomplished then an effort is made to assign the organism to the proper class and type. Unidentified organisms are described as "UI" on the phytoplankton examination sheet. Subscripts are assigned, i.e., "UII", "UI2", "UI3", etc., if more than one kind of unidentified organism are present within a particular class and type.

Counts below 500 cells/ml are generally unreliable. In general, an attempt is made to observe at least 20 organisms while making tallies in strip counts. Any manipulation of the sample (concentration or dilution) adds error. Therefore, on samples with high concentrations, a field count rather than concentrate is performed. On samples with low counts, more strips are counted. Precision is achieved in field counts by determining the coefficient of variation for counts in the number of fields counted and adjusting the number of fields counted to meet an ± 10% error, as outlined in precision calculations (see: "Precision Data").

Diversity indices (see below) compress richness and evenness into a single number. However, information is lost in this process. In an attempt to regain some of this information, ecologists have used evenness or equitability ratios that are usually of the form: measured diversity/standard diversity, where the latter term is the maximum diversity of a community given a certain richness value. A basic problem with this approach is that the value or the ratio is dependent upon the particular characteristics of the diversity index. Thus, biases inherent to the index are incorporated into, and perhaps magnified by, the evenness ratio.

Diversity Indices

Most diversity indices attempt to interdigitate and refine two components of community structure: richness and evenness.

The Shannon Weaver H^{l} is commonly used for two reasons: (1) it is simple in form; and (2) it has a known variance structure. Due to the latter attribute, a t-test for differences in H^{l} between two data sets can be run. The form of the index and its variance structure are taken from Poole (1974) and are presented below.

$$H = \left[-\frac{S}{\sum_{i=1}^{N} pi \cdot \ln pi} \right] - \frac{S-1}{2N} \qquad \text{where } S = \text{ number of taxa} \\ pi = \text{ the proportion of the total number of individuals consisting of the } ith taxon \\ Var. H' = \frac{S}{i=1} pi \cdot \ln^2 pi - \left[\frac{S}{i=1} pi \cdot \ln pi \right]^2 \qquad \text{of the } i^{th} \text{ taxon} \\ Var. H' = \frac{S-1}{2N^2} N = \text{ total number of individuals}$$

Another diversity index commonly used is Simpson's Index which can be defined as: D = 1 - C

where
$$C = \sum_{i=1}^{S} \frac{\text{ni(ni-1)}}{\text{N(N-1)}}$$
 and $S = \text{as above}$ ni = the number of individuals in the ith species
$$N = \text{as above}$$

The term C is an approximation of the probability that two individuals drawn at random from a population of N individuals will belong to the same taxon. The higher this probability, the lower the "diversity" (as measured by this index) of the collection; hence D (equal to 1-C) is used as the index since this parameter will increase with the "diversity" of the sample.

The two indices cited above differ in their sensitivity to changes in richness and evenness. Whereas the Shannon Weaver Index is more an expression of the overall evenness of the community, the Simpson's Index expresses the relative degree of dominance of a few taxa in the community.

3.2 PERIPHYTON

3.2.1 <u>DEFINITION</u>: Periphyton as used here shall mean the attached algal community. Any associated bacteria, fungi, mosses or epiphytic animals are identified to a rudimentary level only. Occasionally, planktonic algae are collected during periphyton sampling in lotic waters. These identifications are reported under the heading periphyton, although, strictly speaking, they are plankton.

3.2.2 OBJECTIVES

- 1. To document the existing periphyton component in lotic and lentic environments and determine dominant types; and
- 2. to evaluate water quality conditions by the use of indicator species.

3.2.3 FIELD SAMPLING

Prior to disturbing the streambed or lakebed, stations (or reaches) selected for qualitative investigation are visually inspected for algal growth. Representative samples are collected from each macrohabitat: pools, riffles, channel, streambank, backwater, open-water; and all substrates: rocks, sand, vegetation, twigs and other debris. Each type of alga encountered is collected using forceps, pipette, knife or by hand. Specimens are placed in labeled glass (or plastic) vials with water from the sampling site, and deposited into a cooler on ice for transportation to the laboratory. Information concerning growth habit and relative abundance of the representative algae are duly noted on field sheets. Photographic documentation of site conditions may also be conducted.

3.2.4 LABORATORY ANALYSES

Log-In Procedure

Each sample is recorded in the algae log book along with the phytoplankton samples. The sample is assigned a number followed by the letter indicating periphyton. This is done in order to distinguish it from phytoplankton samples. Also recorded in the log book are the station number and location, the date collected, initials of the collector, and date analyzed.

Microscopic Analysis

Samples collected in the field are stored in the refrigerator until they are viewed. Specimens are identified within one to two days following collection while they are still alive and healthy. This facilitates identification since preservatives tend to alter the color – and in some cases – the structure of the algae. Identifications are made from wet mounts using a compound microscope equipped with 10x, 20x, 40x, and 100x objectives. Identifications are made using various taxonomic keys to the lowest level possible and recorded on a Periphyton Lab Bench Sheet (see Section 3.2.6). Certain specimens are photographed as a means of documentation and for use in presentations or as a teaching tool. Taxonomic lists of the results are compiled for each survey and published in appropriate reports.

3.3 AQUATIC AND WETLAND VEGETATION

3.3.1 DEFINITION: Aquatic flora as used here pertains to several taxonomic groups including the Characeae (stoneworts and muskgrass); Musci, Hepaticae, and Ricciaceae (mosses, leafy liverworts, thallose liverworts); Osmundaceae (flowering ferns); Equisetaceae (horsetail, scouring rush); Isoetaceae (Quillwort); and the Angiospermae (the seed plants).

3.3.2 OBJECTIVES

- 1. To identify and test reliable methods and procedures for the collection, identification and enumeration of aquatic and wetland vegetation;
- 2. to document existing aquatic plant species and communities; and
- 3. to determine areal coverage and dominant plant types.

3.3.3 FIELD SAMPLING

For riverine habitats, aquatic and wetland vegetation are located and qualitatively mapped by visually examining the streambed, streamside, and immediate riparian areas by walking or wading. A reach of stream approximately 10-meters in length is generally investigated. Each macrohabitat is sampled and the predominant vegetation noted and recorded on standard type field data sheets. A schematic map is prepared for each site. Photographic documentation is sometimes made. Vegetation is generally identified on-site.

The aquatic and wetland plant community in lacustrine habitats is located and mapped by examining the limnetic, shoreline, and littoral areas by boat or waders. Occasional samples are collected at regular intervals on imaginary transects run across open-water areas of the lake or impoundment. All habitats are sampled and the relative abundance of each plant type noted and mapped on prepared outline maps. Representative macrophytes are collected by hand and, in deeper water, by dragging a simple grappling hook with a weight attached to the shaft. An Ekman or Ponar dredge is sometimes used to collect deeply-submerged vegetation. Identifications of most plant specimens are made in the field.

3.3.4 LABORATORY ANALYSES

Vegetation not identified in the field is collected and returned to the laboratory for further analysis using a stereoscopic microscope or hand lens and various taxonomic keys. Representative plant specimens collected from each site are pressed and dried in preparation for permanent mounting. Plant specimens are deposited in the Botanical Reference library of the Technical Services Branch.

3.4 AQUATIC MACROINVERTEBRATES

3.4.1 <u>DEFINITION</u>: The aquatic macroinvertebrate community is defined as the assemblage of invertebrate organisms which can be seen by the unaided eye and retained by a U.S. Standard No. 30 sieve (i.e., 28 meshes per inch; 0.595 mm apertures). All or some life-cycle stages of these animals occur either attached to plants, other animals, debris, or inorganic substrates, or they float or swim in the water column of lentic and lotic waterbodies. Representative members of this community include-but are not limited to sponges, bryozoa, flat worms, segmented worms, arthropods (water mites, crustaceans, insects), and mollusks.

3 4.2 OBJECTIVES

- 1. To provide information for stream classification, assessment of water quality conditions and trends, and direct impact assessment;
- 2. to interpret data using knowledge of the pollution ecology of component taxa (e.g., indicator schemes; biotic indices), or by observing changes in invertebrate community structure (e.g., richness; diversity); and
- 3. to determine the severity of water pollution problems by comparing unimpacted control or reference communities with potentially impacted communities.

3.4.3 FIELD SAMPLING

Qualitative

Qualitative macroinvertebrate sampling for stream classifications or special site assessments involves the use of a variety of sampling devices to collect samples from all available habitats encountered within a sampling site. Generally, D-frame nets are used to sweep aquatic vegetation, collect under cut stream banks, and agitate substrates to dislodge benthic organisms. Depending upon the taxonomic level desired, organisms are identified in the field to family level or placed in jars with 70% ethanol (95% if sample contains sediment materials or debris) for transport to the laboratory where further analyses are conducted.

Rapid Assessment

To obtain a sample for the Rapid Assessment Methodology a D-frame net is pressed against the substrates, and substrate material just upstream and in front of the net is agitated by kicking. This procedure is continued for five minutes while gradually moving upstream. Sampling is executed in areas of comparable substrate and current velocity (usually riffle areas within the central one third of the channel).

At the end of the five minutes of kick-sampling the contents of the net are emptied into a white enamel pan. Organisms clinging to the net are removed, using forcess, and placed in the sample container, as are

organisms on substrate materials too large to fit into the sample container. Once the organisms have been removed, these larger materials are returned to the stream. The remainder of the sample is added to the container and preserved with 95% ethanol, containing 130 mg/l Rose Bengal stain. Completed labels are placed inside each container and attached to the outside. Field notes record the major taxonomic groups encountered during field processing.

Quantitative

When quantitative sampling is required, the following routine is employed:

- 1. Depending on depth, flow, and substrate conditions sampling gear is selected from among Ekman, Petersen and Ponar grab samplers or Surber and Hess substrate samplers. One set of four replicate samples is obtained following a random transect whereby both banks and two quarter points are sampled.
- 2. The substrate obtained is characterized according to particle size and composition, placed into a basin, and mixed thoroughly. When the sample consists of heavily organic or sand-silt type substrate, one-quarter of the sample is randomly selected and retained after mixing. The remaining material is qualitatively examined and discarded. Subsampling is often necessary due to the time required for sorting a large quantity of substrate.
- 3. The sample portion is passed through a standard U.S. No. 30 brass sieve (0.595 mm apertures). Organisms and substrate left behind are placed into labeled plastic or glass wide-mouth containers (approx. liter) and returned alive or preserved with 95% ethanol to the laboratory for further analysis.

3.4.4 LABORATORY ANALYSES

All samples are recorded in a log book upon arrival at the laboratory. Preserved samples are drained on a U.S. Standard No. 30 mesh screen and rinsed with tap water. Live and preserved samples are placed in individual white enamel pans for sorting. Samples for quantitative analyses are preferably sorted alive by removing all benthic organisms manually from the substrate and separating them by taxonomic order into glass vials containing 70% ethanol. For the Rapid Assessment methodology, the contents of the enamel pan are subdivided by scooping material successively (one after the other) into four to eight glass petri dishes until all the material is distributed among the dishes. The number of dishes used depends on the volume of substrate and debris in the sample.

Before picking out organisms, the petri dishes are assigned a number (one to four, if four are used). Numbers are then drawn at random to determine the order of processing. The dish with the number corresponding to the first number drawn is placed on the stage of a stereomicroscope by deliberate orientation (first random field). All organisms within the field of view at low power are picked and placed in labeled vials with 70% ethanol. When all organisms in the field of view have been removed

the dish is moved to another random field for removal of additional organisms. This procedure is repeated until 100 organisms have been selected, moving to the next randomly selected petri dish as required. The remaining sample materials are again sieved on a #30 mesh screen, labeled, and archived in 95% ethanol.

Macroinvertebrate specimens other than chironomids and oligochaetes are identified through examinations using a Wild M5A stereomicroscope equipped with fiber optics lighting. Oligochaetes, chironomid larvae, and chironomid pupae must be mounted on microscope slides before examination with an Olympus BH-2 compound microscope equipped with Nomarski optics. Semi-permanent slide mounts are made by placing the specimens on a 25 x 75 mm microscope slide in CMC-10. The oligochaetes and chironomid larvae are mounted in the CMC-10 without prior clearing. The heads of the chironomid larvae are excised and positioned above the bodies, usually with three specimens under each of two 18 x 18 mm square coverslips per slide. Chironomid pupae are first cleared in 10% KOH (potassium hydroxide) before mounting in CMC-10 with one specimen per 18 x 18 mm slide. The heads of the pupae are also separated from the body once mounted on the slide.

3.4.5 FIELD EQUIPMENT AND SUPPLY LIST

| Vehicles, Boats and Accessories | Field Apparel | |

3.5 FISH

3.5.1 <u>DEFINITION</u>: For the purpose of this standard operating procedure, fish shall include those vertebrate species belonging to the classes Agnatha (jawless fishes), Chondrichthyes (cartilaginous fishes), and Osteichthyes (bony fishes).

3.5.2 OBJECTIVES

- 1. To provide data for surface water quality standards evaluation and the National Pollutant Discharge Elimination System (NPDES) permit program;
- 2. to provide data to assess human health concerns with special regard to fish consumption; and
- 3. to provide complimentary data for assessing water quality impacts to aquatic and semi-aquatic biota.

3.5.3 FIELD SAMPLING

The collection of field data and fish samples for water quality assessment is conducted in close cooperation with the Massachusetts Division of Fisheries and Wildlife and/or Division of Marine Fisheries, as appropriate.

Gill Netting

Gill nets are entanglement gear best described as vertical walls of netting. The typical net used by this Division is of an experimental design. The nets are 38 meters in length and two meters in depth stretched. They usually include a 1.27 cm polypropylene float line and a 23 kg lead line. The net itself is composed of five 7.6 meter monofilament panels. Mesh sizes are: 2.54 cm; 3.175 cm; 3.81 cm; 4.445 cm; and 5.08 cm.

Gill nets are set overnight for approximately 16-20 hours. The Division is experimenting with two-hour sets to minimize the number of unwanted fish collected. Nets are usually set in at least 2.5 m of water and are marked by a buoy on each end. An additional buoy is attached near the center of the net in water less than 2.5 m in depth to warn boaters and/or fishermen of the obstruction.

Electrofishing

Electrofishing using alternating current (a.c.) or direct current (d.c.) electrodes is conducted in streams and in shallow water habitats in lakes, ponds and impoundments. In lotic environments sampling is begun at the lower end of a reach of approximately 50-200 meters in length. Electrically-activated electrodes are swept together along and under stream banks and around rocks, logs and other obstructions. Stunned fish are collected with a dip-net and placed in a tub of stream-water for later processing. Fish sampling in lakes, impoundments and deep rivers is performed using a boat driven slowly forward through shallow areas along the shoreline. In both types of habitats, an estimate of the fish species and numbers missed is noted.

Field Data

For stream habitats, data concerning sample station length, average width and depth, substrate characters, and selected physico-cnemical information are collected. In lentic environments, the approximate area sampled and descriptions of substrate and aquatic vegetation are noted.

PROCESSING

Fish collected from each station in the field are identified, weighed, measured, and labeled, accordingly. Selected specimens are placed in plastic bags and stored on ice in a cooler. Scales from representative fish are collected and placed in "scale envelopes" for further analysis.

Various keys and checklists are used for identification of the fish collected, as appropriate. Individual fish are weighed on scales. When fish are too small to be accurately weighed individually, composite weights are recorded. In all cases, the weight of a fish is the total weight of a whole fish, including any stomach contents. Fish length is measured from the most forward part of the head or snout-with the mouth closed-to the extreme tip of the tail when slightly compressed dorsoventrally at the caudal peduncle.

3.5.4 LABORATORY ANALYSIS

Processing

Fish collected in the field are transported to the laboratory and filleted on a clean wooden board with a sharp fillet knife. Boneless fillets from each side of the fish are attained, and separated from the skin. Fillet samples are wrapped individually and labeled. The cutting board and knife are rinsed in de-ionized water after each fish is processed. Samples for metals analysis are wrapped in plastic (or Saran) wrap. Samples to be tested for PCB's are wrapped in household grade aluminum foil. Fillets to be analyzed for dioxin are wrapped in aluminum foil which has been rinsed with methanol and methlene chloride. Fillet samples (left and right side) from each specimen are placed in separate plastic bags and frozen. One sample is transported, frozen, to the analytical laboratory and tested, while the other is archived for future reference.

3.6 MICROTOX™ ANALYSIS

3.6.1 <u>DEFINITION</u>: The MicrotoxTM toxicity analyzer uses a lyophilized (freezedried) marine bioluminescent bacterium (<u>Photobacterium phosphoreum</u>) which, upon reconstitution, emits a fairly constant level of light. Upon exposure to a toxicant, the level of bioluminescence is diminished in direct proportion to the toxicant concentration.

3.6.2 OBJECTIVES:

- 1. To assess the effectiveness of the Commonwealth's municipally-owned and industrial wastewater treatment plants in eliminating or preventing aquatic toxicity;
- 2. to selectively screen water samples prior to performing more expensive and time-consuming conventional toxicity tests;
- 3. to determine the toxicity of known toxicants using laboratoryprepared solutions of known concentrations; and
- 4. to compare Microtox^{**} test results with results from other toxicity tests.

3.6.3 FIELD SAMPLING

Qualitative

Because the Microtox** system is designed as a quantitative test, qualitative results cannot be determined.

Quantitative

Based on the objectives of the study and an understanding of the short and long-term operations and schedules of the discharger, either grab or composite-type samples are collected for testing. If the suspected toxicity of the source is variable, grab samples collected during peaks of toxicity provide a measure of maximum impact. The compositing technique has an averaging effect, which tends to dilute toxicity peaks, and may provide misleading results when testing for acute toxicity. Composite samples, therefore, are more appropriate for chronic toxicity tests where peak toxicity of short duration is of less concern.

Sample Container Preparation

The 450 ml borosilicate-type glass containers are prepared according to the methods described in the United States Environmental Protection Agency's EPA's Handbook for Sampling and Sample Preservation of Water and Wastewaters (See: "References"), unless the containers are previously unused.

Sample Collection and Handling

Sample containers are rinsed once with sample water prior to collection. An effort is made to fill the sample container to near capacity, with little or no air space. After the container is filled with the sample, a pH reading is taken by the collector with an Orion Model 201 field pH meter. Plastic wrap is placed under the container cap and the sample is put on ice for transport back to the Microtox** laboratory.

Upon arrival at the Microtox²⁴ laboratory, the sample is either (1) tested or (2) refrigerated until the following day and then tested. The maximum holding time for a sample after collection is 24 hours.

3.6.4 LABORATORY ANALYSIS

The basic procedure for the Microtox** system employs duplicates of a non-toxic control and four serial dilutions of the sample. The mean response of the duplicate control is used to normalize the duplicate responses of the four test concentrations of sample when the test results are reduced. Detailed operating procedures for using the Microtox** Analyzer are found in the Microtox System Operating Manual (see: "References").

Laboratory Equipment and Related Supplies

- 1. Beckman Microtox™ model 2055 toxicity analyzer
- 2. strip chart recorder, chart paper
- 3. Microtox[™] reagent (lyophilized)
- 4. Microtox™ reagent diluent
- 5. Microtox™ reconstruction solution
- 6. Microtox** osmotic adjusting solution
- 7. cuvettes, glass, disposable [11.75 mm x 50 mm in size]
- 8. recorder pen, black
- 9. Eppendorf 10 µl pipet, micropipette tips 1-100 µl
- 10. Eppendorf 500 μl pipet, micropipette tips 101-1000 μl
- 11. parafilm, kimwipes
- 12. disposable gloves

3.6.5 QUALITY ASSURANCE

Every tenth sample is tested in duplicate to check consistency and reproducability of results.

3.6.7 INTERPRETATION AND REPORTING OF MICROTOX RESULTS

Test Description

Microtox[™] is the trade name for a particular acute toxicity test. The test is used as a toxics screening tool in addition to other, more traditional methods of analysis.

The Microtox[™] analyzer uses freeze-dried luminescent bacteria as its test organisms. When re-hydrated, these bacteria emit light. To test a water sample for toxicity using Microtox[™], an analyst prepares a series of dilutions of the sample and adds re-hydrated bacteria to these. The light intensity of each sample dilution is measured at preselected time intervals over a 30-minute period and compared with that of a control (bacteria only). It is assumed that changes in light intensity are due to toxicant interference with the biochemical reaction that produces light. Toxicity is then measured as the percent decrease in light intensity of each of the sample dilutions compared with that of the control.

Data Interpretations

The most commonly used result from these tests is the 30-minute EC $_{50}$. This is defined as the sample Concentration causing a $\underline{50}$ % reduction in the measured Effect (light production) over a 30-minute time period. The relationship of the $\underline{\text{EC}}_{50}$ to toxicity is an inverse one; i.e., the lower the $\underline{\text{EC}}_{50}$, the greater the toxicity of the sample.

A useful conversion of the EC_{50} is the Toxic Unit. This is simply the inverse of the EC_{50} multiplied by a factor of 100:

Toxic Units =
$$\frac{100}{EC_{50}}$$
 (%)

Toxic Units approximate the amount of dilution a sample must undergo so as not to induce a toxic response in the test organisms (the Microtox[™] bacteria). As Toxic Units increase so does the relative toxic strength of a sample. The relationship of EC_{50} 's, Toxic Units, and toxicity are demonstrated below:

| <u>EC</u> 50 (%) | Toxic Units | Toxicity |
|------------------|-------------|----------|
| 0.5 | 200 | High |
| 1.0 | 100 | |
| 10.0 | 10 | |
| 100.0 | 1. | Low |

Samples not toxic enough to produce a full 50% decrease in light over the time allotted for the test may still be toxic enough to produce a response in the test. The EC_{20} and EC_{10} (sample concentrations causing a 20% and 10% reduction in light intensity respectively) are reported in order to give the regulator an idea of incipient toxicity — sample dilutions which induce a small, but measurable response in the test.

Results of the Microtox[™] test are also reported for three different periods of exposure: 5-minute, 15-minute, and 30-minute. A decrease in the EC_{50} over time (increase in Toxic Units) usually indicates the presence of persistent toxicants (e.g., metals) in the sample. An increase in the EC_{50} over time (decrease in Toxic Units) suggests that non-persistent toxics (e.g., volatile, biodegradables, photo-or hydrolyzible material) are present at time of sampling.

3.7 CHLOROPHYLL ANALYSIS

3.7.1 <u>DEFINITION</u>: Chlorophyll is a pigment found in plants that allows the organism to use radiant energy for converting carbon dioxide into organic compounds in a process called photosynthesis. Several types of chlorophylls exist and these and other pigments are used to characterize algae. One type, chlorophyll <u>a</u>, is measured for it is found in all the algae. A knowledge of chlorophyll <u>a</u> concentrations provides qualitative and quantitative estimations of phytoplanktonic and periphytic biomasses for comparative assessments of geographical, spacial and temporal variations.

3.7.2 EQUIPMENT NEEDS

1. Fluorometer - either Turner III or the Turner Design 10-005-R field fluorometer is used. They must be equipped with blue lamp F4T5.

Corning filter - 5-60-excitation Corning filter - 2-64-emission Photomultiplier

- 2. Tissue grinder and tube Thomas Tissue Grinder
- 3. Side arm vacuum flask and pump
- 4. Millipore filter holder
- 5. Glass fiber filter: Reeve angel, grade 934H, 2.1 cm
- 6. Centrifuge (Fisher Scientific Safety Centrifuge)
- 7. 15 ml graduated conical end centrifuge tubes with rubber stoppers.
- 8. 90% aqueous acetone
- 9. 2 N HCl
- 10. Saturated magnesium solution in distilled water
- 11. Test tube racks
- 12. Borosilicate cuvettes Turner 111 3" cuvettes
 Turner Design 8" cuvettes
- 13. Aluminum foil
- 14. Test tube brushes conical end
- 15. Parafilm

3.7.3 LOG-IN PROCEDURE

As samples are received they are logged in and assigned a number. The samples can be frozen for further analysis, or the filter ground up for analysis the following day.

3.7.4 SAMPLE PREPARATION

Samples are generally processed as soon as they come into the laboratory, unless there are extenuating circumstances, such as faulty equipment and/or time constraints. Samples not to be analyzed within 24-hours are frozen for future analysis.

The procedure for freezing samples follows:

- 1) Label a 2-inch Whatman petri dish with the sample number using an indelible pen.
- 2) Using tweezers, take a 2.1 cm Reeve Angel, grade 934AH, glass fiber filter and place it on the Millipore filtering flask screen. Do not touch the filter. Attach the glass tube to the filter flask with the metal clamp.
- 3) Shake the sample well.
- 4) Measure out 50 mls of sample or less. If an amount other than 50 mls is used it should be recorded in the chlorophyll data book.
- Pour the measured sample into the filter tube and turn on the vacuum. The sample should pass quickly through the glass fiber filter; therefore more of the sample should be added. If the sample is not filtering through either because too much sediment is present or the algal concentration is too high then less than 50 mls can be filtered. A notation is made in the chlorophyll data book which lists the amount that was filtered.
- 6) Unclamp the filter holder and with tweezers transfer the filter to the previously marked petri dish.
- 7) Cover the petri dish and wrap it in aluminum foil to keep out the light. The petri dish with the glass fiber filter is then stored in the freezer.
- 8) Return the sample bottle to the refrigerator if algal counts or identifications are requested.
- 9) Rinse the graduated cylinder and filter holder in distilled water.

3.7.5 ANALYTICAL PROCEDURE

- 1) Follow steps 2-6 under "Sample Preparation."
- 2) Filter 50 ml (or less if necessary) of sample through a glass fiber filter under vacuum.
- 3) Push the filter to the bottom of tissue grinding tube.
- 4) Add about 3 ml of 90% acetone and 0.2 ml of the MgCO3 solution.
- 5) Grind contents for 3 minutes.
- 6) The contents of the grinding tube are carefully washed into a 15 ml graduated centrifuge tube.
- 7) Bring the sample volume to 10 ml with 90% acetone.
- 8) Test tubes are wrapped with aluminum foil and stored in the refrigerator for 24-hours.
- 9) Test tubes are taken out of the refrigerator and put into the centrifuge.
- 10) Test tubes are then centrifuged for 20 minutes and the supernatant decanted immediately into stoppered test tubes.
- 11) Tubes are allowed to come to room temperature. The temperature is recorded and the samples are poured into a cuvette (3" for Turner 111 and 8" for Turner Design).
- 12) The Turner lll requires a warm-up period of at least one-half hour, while the Turner Design 10-005-R does not require a warm-up period.
- 13) With Turner 111, use a blank of 90% aqueous solution of acetone to zero the instrument. Open the front door of the fluorometer and put in the cuvette containing the 90% acetone and close the door. Press the start switch. The dial should move back to 0; adjustments can be made with the calibration knob. This process should be repeated as often as necessary, i.e., if the blank is not staying on zero; but no alteration should be made until a series of samples is completed.
- 14) The Turner Design must also be zeroed to an acetone blank. 'The sample holder is located at the top of the Turner Design field fluorometer and should be recovered with the black cap after the sample is put in it.
- Readings for both the Turner Ill and the Turner Design should be witnin 20-80% of the scale. This can be achieved by either reducing or increasing the opening to the lamp by moving the know on the right front of the Turner Ill fluorometer. The sensitivity levels are lx, 3x, 10x, and 30x. The sensitivity level must be recorded in the chlorophyll data book in addition to whether the high intensity or regular door was used. After the first reading, 2 drops of 2N HCl is added to the cuvette. A piece of parafilm is used to cover the cuvette which is then inverted four times to mix the sample thoroughly. The sample is re-read and the new value recorded.

The procedure for the Turner Design field fluorometer is basically the same as the Turner III. The sample is put into the cuvette holder and the manual switch used to go from one sensitivity level to the next without opening the door. A reading of between 20-80% is still required for accuracy. Readings are taken before and after acid is added to the sample. The level of sensitivity (1x, 3x, 6x, 10x, 31.6x) must be recorded in the chlorophyll data book, as well as whether the levels were set at 1 or 100.

Calculation of Chlorophyll Concentrations

Chlorophyll concentrations are determined by using the following formulas:

chlorophyll (
$$\mu$$
g/l) = Fs $\frac{rs}{rs-l}$ (Rb-RA)

pheophytin (
$$\mu g/l$$
) = Fs $\frac{rs}{rs-l}$ (rsRa-Rb)

where,

Fs = conversion factor for sensitivity level "s"

rs = before and after acidification ratio of sensitivity level "s"

Rb = fluorometer reading before acidification

Ra = fluorometer reading after acidification

A computer program is used to calculate the chlorophyll concentrations for samples run on the Turner Design fluorometer. A program where the user types in the sensitivity level and the difference between the before and after acidification values is used.

Chlorophyll <u>a</u> and chlorophyll <u>b</u> cannot be differentiated using the Turner lll or the Turner Design fluorometer. In marine phytoplankton samples this is not a problem because chlorophyll <u>b</u> is not found in the Chrysophyta and Pyrrophyta which typically dominate these waters. However, lakes, ponds and impounded rivers are often dominated by the Chlorophyta which have high concentrations of chlorophyll <u>b</u>. Chlorophyll concentrations are now recorded as chlorophyll in mg/m^3 .

3.7.6 INSTRUMENT CALIBRATION

Fluorometers are calibrated using chlorophyll samples provided by the United States Environmental Protection Agency. Calibrations are performed at the start of every field season and redone if any changes are made to the fluorometer such as changing the light bulb.

Samples for chlorophyll analysis are periodically split with another laboratories or run on two separate fluorometers.

4.0 QUALITY ASSURANCE

4.1 PURPOSE AND SCOPE

A quality assurance program has been put in place to validate both the reliability of field and laboratory techniques and the integrity of the biomonitoring data. An essential element of this program is the development of standardized field and laboratory methodologies as outlined in this manual of operating procedures. Standard methods allow for the determination of the accuracy, precision, and variability of biomonitoring data.

Although details pertaining to the quality assurance program have already been presented for individual biomonitoring program elements, major components of the program that are applicable to most biomonitoring activities are summarized in this section.

4.2 INTRALABORATORY QUALITY ASSURANCE

- 1) A staff of adequately trained aquatic biologists is maintained; each with knowledge of the taxonomy and pollution ecology of one or more freshwater communities. These include bacteria, algae, macrophyton, aquatic macroinvertebrates, and fish.
- 2) Collecting gear such as nets, sieves, and grab samplers are inspected and maintained frequently.
- 3) Field and laboratory equipment such as pH and dissolved oxygen meters, microscopes, and fluorometers are maintained and calibrated on a routine basis.
- 4) Field studies are carefully planned in advance to insure that appropriate sites are sampled and that the proper number of samples are obtained to meet survey goals and objectives.
- 5) All samples are clearly labeled at the time of collection, recorded in hard-bound log books, and tracked in a step-wise fashion throughout their processing in the laboratory.
- 6) A reference library is maintained which includes up-to-date identification manuals and keys and both benchmark and recent literature on all aspects of water pollution and its impact on aquatic life.
- 7) A reference specimen collection is maintained for confirming the proper identification of aquatic invertebrates. Similar collections for other communities (e.g., fish) are under development. In addition, many reference specimens and other organisms of interest are photographed and added to an extensive collection of slides to be used as taxonomic aids and for training purposes.

- Aquatic macroinvertebrate, algae, chlorophyll, and MicrotoxTM data are input to computerized data storage and retrieval systems insofar as is allowed by time and personnel constraints. All data sets are carefully proofread and edited during this process. A similar system is proposed for the storage of data generated by the fish sampling program.
- 9) All reporting elements receive peer and/or supervisory review and numerical analyses are checked for mathematical errors.

4.3 INTERLABORATORY QUALITY ASSURANCE

- 1) Reference samples containing known chlorophyll a concentrations, predetermined phytoplankton counts, or known invertebrate taxa are routinely provided to the biomonitoring staff by the United States Environmental Protection Agency (U.S. EPA) for instrumentation calibration and evaluation of laboratory performance.
- 2) Occasionally biological surveys are conducted simutaneously with the USEPA or other state agencies to compare field and laboratory methods and to determine interlaboratory variability of results.
- 3) Specimens that present particular problems with their identification are often sent to expert taxonomists for confirmation. A separate log book is used to record the date and to whom specimens are sent, and, ultimately, the date and details pertaining to the taxonomists response.
